Coffee Consumption and Risk of Stroke in Women

Esther Lopez-Garcia, PhD; Fernando Rodriguez-Artalejo, MD, PhD; Kathryn M. Rexrode, MD, MPH; Giancarlo Logroscino, MD, PhD; Frank B. Hu, MD, PhD; Rob M. van Dam, PhD

Background—Data on the association between coffee consumption and risk of stroke are sparse. We assessed the association between coffee consumption and the risk of stroke over 24 years of follow-up in women.

Methods and Results—We analyzed data from a prospective cohort of 83 076 women in the Nurses' Health Study without history of stroke, coronary heart disease, diabetes, or cancer at baseline. Coffee consumption was assessed first in 1980 and then repeatedly every 2 to 4 years, with follow-up through 2004. We documented 2280 strokes, of which 426 were hemorrhagic, 1224 were ischemic, and 630 were undetermined. In multivariable Cox regression models with adjustment for age, smoking status, body mass index, physical activity, alcohol intake, menopausal status, hormone replacement therapy, aspirin use, and dietary factors, the relative risks (RRs) of stroke across categories of coffee consumption (<1 cup per month, 1 per month to 4 per week, 5 to 7 per week, 2 to 3 per day, and ≥ 4 per day) were 1, 0.98 (95% CI, 0.84 to 1.15), 0.88 (95% CI, 0.77 to 1.02), 0.81 (95% CI, 0.70 to 0.95), and 0.80 (95% CI, 0.64 to 0.98) (P for trend=0.003). After further adjustment for high blood pressure, hypercholesterolemia, and type 2 diabetes, the inverse association remained significant. The association was stronger among never and past smokers (RR for ≥ 4 cups a day versus <1 cup a month, 0.57; 95% CI, 0.39 to 0.84) than among current smokers (RR for ≥ 4 cups a day versus <1 cup a month, 0.97; 95% CI, 0.63 to 1.48). Other drinks containing caffeine such as tea and caffeinated soft drinks were not associated with stroke. Decaffeinated coffee was associated with a trend toward lower risk of stroke after adjustment for caffeinated coffee consumption (RR for ≥ 2 cups a day versus <1 cup a month, 0.89; 95% CI, 0.73 to 1.08; P for trend=0.05).

Conclusions—Long-term coffee consumption was not associated with an increased risk of stroke in women. In contrast, our data suggest that coffee consumption may modestly reduce risk of stroke. (*Circulation*. 2009;119:1116-1123.)

Key Words: coffee ■ nutrition ■ population ■ risk factors ■ stroke ■ women

Recent analyses support the hypothesis that coffee consumption does not increase the risk of coronary heart disease.¹⁻³ In addition, increasing evidence suggests that coffee consumption may protect against type 2 diabetes.⁴⁻⁸ However, data on the relation between coffee consumption and stroke are sparse. No association has been found between coffee and risk of total stroke among middle-aged healthy men⁹ and among patients with type 2 diabetes.¹⁰ By contrast, another study found that consumption of coffee was associated with an increased risk of ischemic stroke among hypertensive men.¹¹ Finally, in a recent study of male smokers, an association between high coffee consumption and a lower risk of stroke was observed.¹² To the best of our knowledge, the association between coffee and stroke among women has not been examined previously.¹³

Clinical Perspective p 1123

In this study, we assessed the association between long-term coffee consumption and risk of stroke over 24 years of follow-up in US women. To determine whether caffeine or other compo-

nents in coffee were responsible for the observed associations, decaffeinated coffee and other caffeinated beverages also were examined. Moreover, given that several studies have associated coffee consumption with increased risk of hypertension¹⁴ and hypercholesterolemia^{15,16} but reduced risk of type 2 diabetes,¹⁷ we examined whether the association between coffee consumption and stroke was modified by these vascular risk factors.

Methods

Study Population

We used data from the Nurses' Health Study (NHS), the full details of which have been published elsewhere.¹⁸ Briefly, this cohort was established in 1976, and information from the participants has been updated every 2 years. We used 1980 as the baseline because this was the first year in which information on diet was collected. For the present analysis, we excluded participants with a history of stroke, coronary heart disease, diabetes, or cancer at baseline and those with no information about coffee consumption at baseline ($n=879$), leaving 83 076 women. The Harvard School of Public Health and Brigham and Women's Hospital Human Subjects Committee Review boards approved the study protocol.

Received October 3, 2008; accepted January 9, 2009.

Assessment of Coffee Consumption

Food frequency questionnaires were sent to the NHS participants in 1980, 1984, 1986, 1990, 1994, 1998, and 2002. In each questionnaire, participants were asked how often on average during the previous year they had consumed coffee and tea. Decaffeinated coffee and different types of caffeinated soft drinks were first assessed in 1984. Using the US Department of Agriculture food composition data supplemented with other sources, we estimated that the caffeine content was 137 mg per cup of coffee, 47 mg per cup of tea, 46 mg per can or 12-ounce bottle of soft drink, and 7 mg per 1-ounce serving of chocolate candy. We assessed the total intake of caffeine by summing the caffeine content for a unit of each food during the previous year multiplied by a weight proportional to the frequency of its consumption. In our validation study, we obtained high correlations between consumption of coffee and other caffeinated beverages estimated from the food frequency questionnaire and consumption estimated from repeated 1-week diet records (coffee, $r=0.78$; tea, $r=0.93$; caffeinated soft drinks, $r=0.85$).¹⁹ For the present analysis, coffee consumption was categorized into 5 groups: <1 cup per month, 1 cup per month to 4 cups per week, 5 to 7 cups per week, 2 to 3 cups per day, and ≥ 4 cups per day. Food frequency questionnaires also were used to assess the consumption of other foods. Nutrient values were derived from the foods reported and were energy adjusted using the residual method.²⁰

Ascertainment of Stroke

Incident stroke was defined as the first nonfatal stroke or stroke death occurring after the baseline questionnaire in 1980 but before June 1, 2004. Women who reported a stroke were asked for permission to access medical records, which were reviewed by a physician without knowledge of the participant's exposure status. Stroke was classified according to criteria of the National Survey of Stroke,²¹ which requires evidence of a neurological deficit with sudden or rapid onset that persisted for >24 hours or until death. Cerebrovascular pathology caused by infection, trauma, or malignancy was excluded, as were silent strokes discovered only by radiological imaging. Strokes were classified as follows: ischemic stroke (thrombotic or embolic strokes), hemorrhagic stroke (subarachnoid or intraparenchymal hemorrhage), or stroke of undetermined subtype. For each type of stroke, the diagnosis was classified as definite when a computed tomography scan, magnetic resonance imaging, angiography, surgery, or autopsy had confirmed the lesion; otherwise, stroke was classified as probable. Computed tomography or magnetic resonance imaging reports were available for 89% of those with medical records. Cases in which medical record release was refused or for which medical records were unavailable were classified as probable stroke of undetermined type. In these analyses, 1909 cases of a first nonfatal stroke were identified: 1364 (71.4%) were confirmed by medical record review, and 545 (28.6%) were classified as probable, corroborated by letter or by telephone.

Deaths were identified through information provided by the next of kin or postal authorities or by systematic searches of the National Death Index. Classification of fatal stroke was confirmed by review of hospital records, autopsy, or death certificate. If information was limited to death certificates or information provided by next of kin with no medical records available, cases were classified as probable. In this analysis, of 371 fatal strokes, 310 (83.5%) were confirmed by medical records, and 61 (16.5%) were classified as probable, corroborated by telephone information provided by next of kin or by death certificates.

Of 2280 total strokes, 1674 (73.4%) were confirmed on the basis of medical records, and 606 (26.6%) were classified as probable on the basis of supporting information. Similar results were obtained when confirmed strokes were examined separately; therefore, confirmed and probable cases were combined for total stroke analyses.

Assessment of Medical History, Anthropometric Data, and Lifestyle Factors

In the baseline questionnaire, we requested information about age, weight and smoking, menopausal status and use of postmenopausal hormone therapy, aspirin use, and personal history of stroke, coronary heart disease, cancer, type 2 diabetes mellitus, hypertension, and hypercholesterolemia. This information has been updated in the biennial follow-up questionnaires. Height was ascertained on the 1976 enroll-

ment questionnaire. Information about treatments for hypertension and hypercholesterolemia was collected in 1988, 1994, 1996, 1998, and 2002. Body mass index was calculated as weight in kilograms divided by the square of height in meters. Physical activity was assessed biennially and reported in hours per week of moderate (eg, brisk walking) and vigorous (eg, strenuous sports and jogging) exercise. Alcohol intake was assessed every 4 years and was measured in grams per day. Standard drinks of alcoholic beverages were specified as a can/bottle or glass for beer, 4-oz glass for wine, and 1 drink or shot for liquor. Detailed information on the validity and reproducibility of self-reported weight, physical activity, and alcohol consumption has been reported elsewhere.²²⁻²⁴ In addition, self-reported diagnosis of hypertension, hypercholesterolemia, and type 2 diabetes was found to be reliable in the NHS cohort.^{25,26}

Statistical Analysis

We classified participants according to levels of coffee consumption. We calculated person-years of exposure from the date of return of the baseline questionnaire to the date of death or June 1, 2004, whichever came first. To reduce within-subject variation and to best represent long-term diet, we used the cumulative average of coffee consumption from all available dietary questionnaires up to the start of each 2-year follow-up interval²⁷; thus, the average of the 1980 and 1984 intakes was used for the follow-up between 1984 and 1986; the average of the 1980, 1984, and 1986 intakes was used for the follow-up between 1986 and 1990, and so on. When a food frequency questionnaire had a missing value for coffee, we used the value from the previous questionnaire.

We used Cox proportional-hazards models to investigate the association between coffee consumption and incidence of total, hemorrhagic, and ischemic stroke. To control as finely as possible for confounding by age and calendar time, we stratified the analysis jointly by age in months at start of follow-up and calendar year of the current questionnaire cycle. We used hazard ratios to estimate relative risks (RRs) in each category of coffee consumption compared with participants in the lowest category of coffee consumption. Multivariable models were adjusted for smoking, body mass index, physical activity, alcohol intake, menopausal status and use of postmenopausal hormone therapy, aspirin use, and dietary factors that have been associated with risk of hypertension and stroke (total energy intake, calcium, potassium, sodium, folate, glycemic load, cereal fiber, whole grain intake, fruits, vegetables, and fish consumption).²⁸ An additional analysis was performed to further adjust the association between coffee and stroke for potential biological mediators, including hypertension, hypercholesterolemia, and type 2 diabetes mellitus. To test for linear trends across categories, we modeled coffee consumption as a continuous variable using the median value of each category of coffee consumption.

We conducted stratified analyses by categories of hypertension, hypercholesterolemia, type 2 diabetes mellitus, smoking, alcohol consumption, and body mass index. We examined the interaction between coffee and the categories of the stratification variables with stroke by using likelihood-ratio tests, which compared the nested models with and without cross-product interaction terms. Finally, we studied the association of caffeine, tea, caffeinated soft drinks, and decaffeinated coffee consumption with stroke. All analyses were performed with SAS software, version 9.1 (SAS Institute Inc, Cary, NC).

This manuscript follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) recommendations.²⁹ The authors had full access to and take responsibility for the integrity of the data. All authors have read and agree to the manuscript as written.

Results

During 24 years of follow-up, we documented 2280 stroke events, including 426 hemorrhagic, 1224 ischemic, and 630 undetermined stroke events. In Table 1, we present the characteristics of the NHS participants by levels of coffee consumption in 1990, roughly the midpoint of the follow-up period. Frequent caffeinated coffee consumption was strongly associated with smoking. In addition, women who consumed more coffee were more likely to drink alcohol. Women in the upper categories of caffeinated coffee consumption followed a diet higher in potassium with a lower

†Aspirin use ≥1 times per week.

glycemic load, factors that may reduce the risk of stroke. In contrast, women with higher coffee consumption also showed lower intakes of folate and whole grains, which may increase the risk of stroke. Caffeinated coffee was consumed by 84% of the subjects in the cohort, whereas 50% of study participants were consumers of decaffeinated coffee, 78% drank tea, and 54% drank caffeinated soft drinks.

In age-adjusted analyses, higher caffeinated coffee consumption was not associated with risk of total stroke (Table 2). However, after adjustment for smoking and other confounders, we found that women who consumed 2 to 3 cups of coffee per day had a 19% lower risk of stroke than women in the lowest

category of consumption, whereas women consuming ≥4 cups of coffee per day had a 20% lower risk of stroke (P for trend=0.003). After adjustment for hypertension, hypercholesterolemia, and type 2 diabetes, the results were similar although the RR for consumption of ≥4 cups per day became nonsignificant. Moreover, when we analyzed types of strokes, we observed a suggestion of an inverse association for caffeinated coffee consumption and risk of ischemic stroke (P for trend=0.06) with similar attenuation after controlling for the potential biological mediators.

One prior report had suggested a detrimental effect of caffeinated coffee consumption on stroke among hypertensive

*Adjusted for the following: age (5-year categories); smoking status (never, past, and current 1 to 14, 15 to 24, and ≥25 cigarettes a day); body mass index (<23.0, 23.0 to 24.9, 25.0 to 27.9, 28.0 to 29.9, ≥30.0 kg/m²); physical activity (<1.0, 1.0 to 1.9, 2.0 to 3.9, 4.0 to 6.9, ≥7.0 h/wk); alcohol intake (never, 0.1 to 4.9, 5.0 to 9.9, 10.0 to 14.9, 15.0 to 29.9, ≥30.0 g/d); menopausal status and use of hormone replacement therapy (premenopausal women, postmenopausal without hormone therapy, postmenopausal with past hormone therapy, postmenopausal with current hormone therapy); aspirin use; total caloric intake; quintiles of calcium, potassium, sodium, and folate intake; glycemic load; whole grain intake; and tertiles of fruits, vegetables, and fish consumption.

†Additional adjustment for potential intermediates: high blood pressure, hypercholesterolemia, and type 2 diabetes mellitus.

men¹¹; by contrast, in our cohort, we found an inverse association among nonhypertensive women and no association among hypertensive participants. However, the formal test for interaction was nonsignificant ($P=0.29$; Table 3). Similarly, trends were nonsignificant for diabetic and hypercholesterolemic women, although formal interaction terms were negative. Moreover, the inverse association between caffeinated coffee consumption and stroke was observed only among nonsmokers and past smokers but not current smokers (P for interaction=0.05). Being obese or drinking alcohol did not significantly modify the association between coffee consumption and stroke.

We next studied the relation between total caffeine intake and risk of stroke and again observed an inverse association (Table 4). However, we cannot attribute this effect solely to caffeine because caffeinated coffee consumption and total caffeine intake are highly correlated ($r=0.92$). Thus, to elucidate whether caffeine was responsible for the reduced risk of stroke among women consuming caffeinated coffee, we assessed the effect of other beverages containing caffeine such as tea and caffeinated soft drinks on stroke separately; no association was found (Table 4). Finally, we assessed associations for decaffeinated coffee, which has a composition similar to that of caffeinated coffee except for caffeine. We observed a lower risk of stroke in women who drank moderate amounts of decaffeinated coffee after controlling the analyses for caffeinated coffee consumption.

Because it is possible that some of the effects of caffeinated coffee may be short term, secondary analyses were performed to

assess the association between the most recently reported coffee consumption and stroke; the results were similar to those reported above using cumulative caffeinated coffee consumption. We also stopped updating information on coffee consumption when hypertension, hypercholesterolemia, cancer, diabetes, or heart diseases were diagnosed during the follow-up, with similar results. In addition, no appreciable change in the association was observed after adjustment for medication to treat hypertension (diuretics, β -blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, and others) and hypercholesterolemia (statins and others). Finally, analyses using only confirmed strokes as the end point gave results comparable to the analyses using both confirmed and probable cases of stroke.

Discussion

In the present large cohort of women, those who drank moderate to high amounts of coffee had a lower risk of stroke than those who did not consume coffee. This association was only partially mediated by potential biological mediators, including high blood pressure, hypercholesterolemia, and type 2 diabetes mellitus. Higher consumption of decaffeinated coffee, but not tea or caffeinated soft drinks, also was associated with a generally lower stroke risk, supporting the hypothesis that components in coffee other than caffeine may lower risk of stroke.

Few studies have addressed the association between coffee consumption and risk of stroke (Table 5). Those analyses have been performed in groups with very different risks of stroke such as

*Additional adjustment for number of cigarettes per day. The number of events is different because of missing values for smoking status.

healthy people, patients with type 2 diabetes, hypertensive individuals, and even smokers. In our analyses, we were able to assess long-term coffee consumption in a large population of women and to evaluate possible differences in the association between healthy participants and those with the vascular risk factors listed above.

Hypertension is a major risk factor for stroke.¹³ However, the relationship between long-term coffee consumption and hypertension remains uncertain because few cohort studies have analyzed this association. Klag et al,¹⁴ using the Johns Hopkins Precursors Study, found that consumption of coffee was cross-sectionally associated with a slightly higher blood pressure, although the association with incident hypertension was unclear. Using data from the NHS and NHS II, Winkelmayr et al³⁰ found that coffee consumption was not associated with an increased risk of hypertension in women (RR for consumption of ≥6 cups per day, 0.88 [95% CI, 0.80 to 0.98] versus <1 cup a day in NHS and 0.91 [95% CI, 0.80 to 1.04] in NHS II). Hu et al³¹ examined the association between coffee and the incidence of antihypertensive drug use. They concluded that consumption of >2 cups of coffee per day increased the risk of antihypertensive drug treatment (RRs for consumption of 2 to 3, 4 to 5, 6 to 7, and ≥8 cups of coffee a day were 1.29 [95% CI, 1.09 to 1.54], 1.26 [95% CI, 1.06 to 1.49], 1.24 [95% CI, 1.04 to 1.48], and 1.14 [95% CI, 0.94 to 1.37] compared with 0 to 1 cup a day). Finally, Uiterwaal et al³² found that female abstainers and heavy consumers (>6 cups of coffee per day) had a lower risk of hypertension than moderate consumers (1 to 3 cups per day). Most of these studies suggest that although caffeine intake acutely increases blood pressure,³³ regular exposure to caffeine can attenu-

ate this effect. In addition, a study found that consumption of 3 cups of coffee per day increased the risk of stroke among hypertensive patients¹¹ (RR, 2.1; 95% CI, 1.2 to 3.7). This study pointed to caffeine as potentially responsible for this association by increasing cardiovascular resistance and decreasing cerebral blood flow, which impair the already damaged vascular system in these patients.³⁴ In our study, an inverse association between coffee consumption and risk of stroke was apparent only in women without hypertension, but no increase in risk of stroke was seen among hypertensive participants. More research is necessary to elucidate whether coffee may have a detrimental effect on these patients.

We also examined the effect of coffee on stroke separately in women with and without diabetes mellitus. Long-term studies have consistently found an association between higher coffee consumption and lower risk for type 2 diabetes.¹⁷ One study has assessed the effect of coffee on fatal stroke among diabetic patients, finding no association even with consumptions as high as 7 cups per day.¹⁰ Similarly, in our study, we did not find an association between coffee and stroke in the subsample of diabetic patients. Although coffee has been shown to have a beneficial effect on glucose metabolism,¹⁷ the null association between coffee and stroke found in these patients may reflect the important effect of diabetes on atherosclerosis and hypercoagulability, among other vascular alterations,³⁵ which neutralizes any beneficial effect of coffee in this population.

Hypercholesterolemia is another important risk factor for stroke. Although short-term clinical trials have confirmed the cholesterol-raising effect of diterpenes present in boiled coffee,¹⁵ no long-term studies have assessed this association.

†Models adjusted for the same covariates as in model 1 (Table 2), plus caffeinated coffee consumption.

‡Follow-up from 1984.

In a previous cross-sectional study,¹ we did not find increased levels of total, low-density lipoprotein, and high-density lipoprotein cholesterol among individuals consuming non-paper-filtered coffee compared with nonconsumers. In the present study, we found an inverse association between coffee and stroke among participants without hypercholesterolemia but not among those with the risk factor. We can only speculate that the effect of coffee might be of a lower relevance for patients with a higher degree of atheromatosis.

Finally, smoking is a strong confounder in the study association because it is a potent risk factor for stroke and because smoking is more frequent among coffee drinkers. Therefore, stratified analyses were performed to more thoroughly eliminate residual confounding. Coffee consumption was associated with a substantially lower risk of stroke among nonsmokers but not among current smokers. We hypothesize that the potential benefit of coffee reducing the risk of stroke cannot counterbalance the detrimental effect of smoking on health.

Several mechanisms might help to explain the reduced incidence of stroke that we observed among individuals who consumed coffee. Some substances in coffee may have beneficial effects on glucose metabolism, inflammation, and endothelial dysfunction. For example, habitual coffee consumption has been associated with higher insulin sensitivity.³⁶ In addition, we previously reported an inverse association of caffeinated coffee consumption with surface leukocyte adhesion molecules (E-

selectin) and with C-reactive protein, an inflammatory marker, in diabetic women, as well as an inverse association of decaffeinated coffee consumption with C-reactive protein in healthy women.³⁷ Furthermore, the phenolic compounds of coffee (chlorogenic acid, ferulic acid, and p-coumaric acid) have a strong antioxidant capacity, which may improve endothelial function.³⁸ The modest inverse association between decaffeinated coffee consumption and risk of stroke in our study supports the hypothesis that components in coffee other than caffeine may be responsible for the potential beneficial effect of coffee on stroke risk.

The present study had several strengths for the examination of the association between coffee consumption and risk of stroke. First, the study included multiple repeated measures of coffee consumption, limiting misclassification. Some measurement error in the assessment of coffee consumption may still have occurred because data on consumption were self-reported. However, results from our validation study indicate that coffee was among the most accurately reported foods in the dietary questionnaire.¹⁹ Second, we were able to control for potential confounders in more detail than in earlier studies because information on risk factors has been updated every 2 years; however, residual confounding by other factors associated with coffee consumption cannot be excluded. Third, data collection on incident strokes was thorough, and a high percentage of events were confirmed by imaging studies. On the other hand, the possibility that reverse causation may have biased our results

Table 5. Cohort Studies Addressing the Association Between Caffeinated Coffee Consumption and Risk of Stroke*

Author, Country	Subjects	Age, y	n	Exposure	Outcome	Cases, n	Mean Follow-Up, y	Adjustment for Confounding	Multivariate-Adjusted Result	Comments
Grobbée et al, ⁹ US	Healthy men	40–75	45 589	Caffeinated coffee at baseline	Fatal and nonfatal stroke	54	2	Age, SMK, BMI, history of diabetes, alcohol consumption, parental history of MI, specific health profession, and dietary intake of energy, cholesterol, and saturated, monounsaturated, and polyunsaturated fat	For consumption of ≥ 4 cups/d, the RR of fatal and nonfatal stroke was 0.28 (95% CI, 0.06–1.26) vs nonconsumption	No association between coffee and fatal and nonfatal stroke
Bidel et al, ¹⁰ Finland	Diabetic men	25–74	3837	Total coffee at baseline	Fatal stroke	210	20.8	Age, sex, BMI, SBP, serum total cholesterol, education, SMK, and alcohol and tea consumption	For consumption of ≥ 7 cups/d, the RR of fatal stroke was 0.90 (95% CI, 0.56–1.45) vs 0–2 cups/d	No association between coffee and fatal stroke.
Hakim et al, ¹¹ US	Hypertensive and nonsmoking men	55–68	499	Total coffee at baseline	Ischemic stroke, hemorrhagic stroke	76	25	Age, SBP, serum total cholesterol, triglycerides, history of diabetes, alcohol use, and physical activity	For consumption of 24 oz/d, the RR of ischemic stroke was 2.1 (95% CI, 1.2–3.7) vs nonconsumption; RR for hemorrhagic stroke not provided	Positive association between coffee and ischemic stroke; no association between coffee and hemorrhagic stroke
Larsson et al, ¹² Finland	Male smokers	50–69	26 556	Total coffee at baseline	Ischemic stroke Intracerebral hemorrhages Subarachnoid hemorrhages	2702 383 196	13.6	Age, vitamin supplementation use, SMK, BMI, SBP, DBP, serum total cholesterol, HDL, history of diabetes and CHD, physical activity, and alcohol and tea consumption	For consumption of ≥ 8 cups/d, the RR of ischemic stroke was 0.77 (95% CI, 0.66–0.90), the RR of intracerebral hemorrhages was 0.98 (95% CI, 0.66–1.47), and the RR of subarachnoid hemorrhages was 1.18 (95% CI, 0.63–2.20) vs < 2 cups/d	Inverse association between coffee and ischemic stroke; no association between coffee and intracerebral or subarachnoid hemorrhage

SMK indicates smoking; BMI, body mass index; MI, myocardial infarction; SBP, systolic blood pressure; DBP, diastolic blood pressure; HDL, high-density lipoprotein; and CHD, coronary heart disease.

*Obtained from a MEDLINE search through June 2008 using the key words “coffee” and “caffeine” in combination with “stroke.”

should be considered. For example, women who were diagnosed with hypertension may have lowered their consumption of caffeinated coffee as a result of the diagnosis. We addressed this issue by examining the association between coffee and risk of stroke among nonhypertensive women only, as well as performing additional analyses that stopped updating consumption when hypertension was diagnosed. The associations between coffee and risk of stroke were similar to those in the main analysis.

Conclusions

In the present long-term follow-up study, coffee consumption was not associated with an increased risk of stroke. In contrast, we observed that women who regularly consumed coffee had a modestly lower risk of stroke than nonconsumers. Our data support the hypothesis that components in coffee other than caffeine may lower the risk of stroke,

although the association was modest and the biological mechanism is unclear. These results should be supported by further research before the possible implications for public health and clinical practice are considered.

CLINICAL PERSPECTIVE

Data on the relation between coffee consumption and stroke are sparse. We followed up a large population of US women during 24 years, assessing coffee intake repeatedly. For consumption of ≥ 2 cups of coffee per day, a 20% reduction in the risk of stroke was observed. After additional adjustment for potential mediators of the relation between coffee consumption and stroke such as high blood pressure, hypercholesterolemia, and type 2 diabetes mellitus, the inverse association was slightly attenuated. The association was stronger among nonsmokers than among current smokers. Decaffeinated coffee also was associated with lower risk of stroke. By contrast, other drinks containing caffeine were not associated with stroke. Our results provide evidence that coffee consumption does not increase the risk of stroke in women. In contrast, our data suggest that coffee consumption may modestly reduce the risk of stroke.
